A Diffusion Tensor Imaging Group Study of the Spinal Cord in Multiple Sclerosis Patients With and Without T2 Spinal Cord Lesions

Wim Van Hecke, PhD,1,2,* Guy Nagels, MD, PhD,3–5 Griet Emonds, MSc,2,6 Alexander Leemans, PhD,7,8 Jan Sijbers, PhD,1 Johan Van Goethem, MD, PhD,2 and Paul M. Parizel, MD, PhD2

Purpose: To examine the T2-normal appearing spinal cord of patients with multiple sclerosis (MS) using diffusion tensor imaging.

Materials and Methods: Diffusion tensor images of the spinal cord were acquired from 21 healthy subjects, 11 MS patients with spinal cord lesions, and 10 MS patients without spinal cord lesions on the T2-weighted MR images. Different diffusion measures were evaluated using both a region of interest (ROI)-based and a diffusion tensor tractography-based segmentation approach.

Results: It was observed that the FA, the transverse diffusivity λt, and the ratio of the longitudinal and transverse diffusivities (λl/λt) were significantly lower in the spinal cord of MS patients with spinal cord lesions compared with the control subjects using both the ROI method (P = 0.014, P = 0.028, and P = 0.039, respectively) and the tractography-based approach (P = 0.006, P = 0.037, and P = 0.012, respectively). For both image analysis methods, the FA and the λl/λt values were significantly different between the control group and the MS patient group without T2 spinal cord lesions (P = 0.013).

Conclusion: Our results suggest that the spinal cord may still be affected by MS, even when lesions are not detected on a conventional MR scan. In addition, we demonstrated that diffusion tensor tractography is a robust tool to analyze the spinal cord of MS patients.

Key Words: spinal cord; diffusion tensor imaging; diffusion tensor tractography; multiple sclerosis

MULTIPLE SCLEROSIS (MS) is a chronic demyelinating disease of the central nervous system, which is characterized by both inflammatory and neurodegenerative processes. Nowadays, magnetic resonance (MR) imaging is increasingly used in the diagnosis of MS patients with spinal cord involvement (1). In addition, MR can also be useful in patients who do not have clinical spinal cord involvement, because asymptomatic spinal cord lesions are common in MS and uncommon in other WM disorders (2). However, the spinal cord lesion information as obtained by a conventional MR examination does not always correlate well with the clinical disability of the patient and/or with histological information (3–5). It has been demonstrated that the white matter (WM) regions that appear normal on conventional MR images, referred to as normal-appearing WM (NAWM), are also involved in the MS disease process (6–8). In this context, diffusion tensor imaging (DTI) can provide complementary diagnostic information regarding the microstructural WM organization in MS lesions and NAWM (8,9). This technique is based on the fact that water molecules have a larger probability to diffuse along the axonal structures than perpendicular to them. Recent studies demonstrate the potential of quantitative DTI parameters, such as the fractional anisotropy (FA), which is a normalized measure of the degree of anisotropy, and the mean diffusivity (MD), that is, the averaged diffusion, for detecting WM alterations in patients with MS (10–14). Because the spinal cord is frequently involved in MS, DTI can be regarded as a valuable technique to examine
WM alterations in the spinal cord of patients with MS. However, in contrast to the potential of such a DTI study of the spinal cord, only a limited number of papers are published regarding this topic (15–22). In this context, it is known that several factors hamper a robust DTI study of the spinal cord, such as restricted diffusion tensor (DT) image resolution, the small size of the spinal cord, and artifacts related to cardiac and respiratory motion, and magnetic field inhomogeneities (23,24). As a result, a relatively large number of voxels contain a combined signal originating from both the spinal cord and the cerebrospinal fluid (CSF), which is also known as a partial volume effect (PVE) (25).

In a preliminary study of three MS patients, Clark et al demonstrated a significant FA decrease and MD increase in MS cord lesions using a region of interest (ROI) -based approach (15). To increase the robustness and the reproducibility of the image processing, Valsasina et al and Agosta et al performed a histogram analysis on the central slice of the sagittal images (16,17). In these studies, a significant FA decrease was observed in the cervical spinal cord of MS patients, compared with healthy subjects. This histogram analysis approach was also adopted by Benedetti et al in a DTI study of MS patients and patients with neuromyelitis optica (18). Hesseltine et al. reported a significant FA decrease in the NAWM of patients with MS in the lateral, central, and posterior regions of the spinal cord at the C2–C3 level compared with healthy subjects (19). Their image processing method was based on the manual placement of circular ROIs on a single axial slice. Ohgiya et al demonstrated a reduced FA in lesions and NAWM regions of MS patients compared with healthy subjects by manually placing small, ovoid ROIs at the C2–C3, C3–C4, and C4–C5 level (20). Recently, Ciccarelli et al demonstrated that the FA is reduced in MS patients compared with normal controls, using diffusion tensor tractography (21).

Previous DTI studies of the spinal cord in MS patients focused on the examination of diffusion measures in spinal cord lesions or in NAWM near these lesions using ROIs. We hypothesize that the spinal cord can also be involved in the disease when no lesions are reported on the conventional MR scans. In addition, we hypothesize that a tractography-based spinal cord segmentation method is more reliable and sensitive to detect diffusion alterations in the normal appearing spinal cord of MS patients compared with the generally applied ROI approach (26). The aim of this work was, therefore, to examine the spinal cord diffusion properties of MS patients without spinal cord lesions or in NAWM near these lesions using diffusion tensor tractography. To the best of our knowledge, this is the first quantitative DTI study of the cervical spinal cord that appears entirely normal on a conventional MR examination in patients with MS.

**METHODS**

**Subjects**

Diffusion tensor measurements of the cervical spinal cord (C1–C5) were acquired from 21 MS patients (age: 38 ± 9 years; 8 males, 13 females). 21 sex- and age-matched healthy subjects were additionally scanned (age: 40 ± 10 years; 8 males, 13 females). All healthy subjects had a normal appearing spinal cord on conventional T2-weighted MR images. An informed consent was signed by all participants.

In 11 of the MS patients, which we will refer to as MS patient group 1, one or more lesions were detected in the spinal cord on conventional MR images. In the other 10 MS patients, which will be referred to as MS patient group 2, no spinal cord lesions were detected on the conventional MR scan. Twelve patients had relapse-remitting MS (6 in MS patient group 1 and 6 in MS patient group 2), 9 patients had secondary progressive MS (5 in MS patient group 1 and 4 in MS patient group 2). There was no clinical suspicion of an acute MS attack in any of the patients at the time of imaging.

**MRI Acquisition**

Axial diffusion tensor images were obtained on a 1.5 Tesla (T) MR scanner (Siemens, Erlangen, Germany) using a single-shot SE-EPI sequence with the following acquisition parameters: TR: 10.4 s; TE: 100 ms; diffusion gradient: 40 mT/m; FOV = 256 × 256 mm² matrix size: 128 × 128; number of slices = 30; image resolution = 2 × 2 × 2 mm³; b = 700 s/mm²; acquisition time: 12 min 18 s. Diffusion measurements were performed along 60 directions (+ 10 nondiffusion weighted (b0) images) for a robust estimation of FA, tensor orientation, and MD (27). The diffusion tensors were non-linearly estimated based on the Levenberg-Marquardt optimization method (27).

Parallel imaging, integrating a combination of two elements of the CP (circular polarization) spine coil and one element of the neck coil, was used to reduce the effect of distortions on the data (28,29). Although magnetic susceptibility variations may not be significant deep inside the brain, they can constitute a real problem near the spinal cord. To quantify the effect of these susceptibility variations, magnetic field maps were acquired for each subject. The field map gives a direct representation of the static field inhomogeneity, allowing the measurement of the spatial misregistration associated with each point of an image. This field map was obtained by computing the phase difference between two images acquired with different echo times (30,31). When these distortions exceeded 1 voxel in the tissue of interest, as calculated from the field maps, the data set was excluded from the analysis. A linear or nonlinear image registration to correct for motion artifacts and geometrical distortions was not included in this study, because the limited image information did not allow a robust registration. Instead, all data sets were analyzed visually to check for distortions. As a result, data sets of 2 subjects were excluded from the analysis due to a significant signal dropout.

An example of the diffusion weighted images is provided in Figure 1. A contour that delineates the spinal cord is drawn on a sagittal slice of the FA map. Exactly the same contour is also placed on the same sagittal slice of the nondiffusion weighted image, the first DW image, the mean DW image, and the MD map. Diffusion tensor estimation, tractography, visualization, and
the orientational diffusion information that is present used to further segment the spinal cord tissue, using subjects (26). Diffusion tensor tractography is thus covered by fiber tracts without any interruptions in all performed to make sure that the whole spinal cord was Van Hecke et al, and a careful visual inspection was tracts. The tractography parameters were defined as in (38) and Melhem et al (39). Subsequently, all quantita-
mal angle between two consecutive tract directions was voxel in which the step size was 1 mm (37). The maxi-
matic approach could be applied (26).

Diffusion Parameters of Interest

Multiple quantitative diffusion parameters were ana-
yzed in all subjects. FA and MD were calculated and averaged over all selected voxels for all subjects. In addition, the longitudinal ($\lambda_1$) and transverse ($\lambda_2$) dif-
fusivities, and the ratio of the longitudinal versus trans-
verse diffusivities ($\lambda_1/\lambda_2$) were also computed, because it has been suggested that this ratio can better differenti-
ate between healthy and diseased subjects (33–36).

Image Analysis

It is generally known that it is difficult to determine spinocord diffusion measures, because many voxels at the edge of the spinal cord contain a signal of both the spinocord tissue and CSF. In a first image analysis approach, ROIs were manually placed on each axial slice, thereby carefully delineating the spinal cord to avoid the inclusion of PVE contaminated voxels in the analysis. All ROIs were defined on the axial slices of the FA maps, color encoded for the diffusion direction, because they provided the best contrast between the spinocord tissue and the surrounding CSF (see Fig. 2a,b).

In a second image analysis method, also referred to as the tract-based segmentation approach, diffusion ten-
sor tractography was performed on the spinal cord that was first manually delineated by ROIs (see Fig. 2c) (26).

A standard deterministic streamline-based fiber tracing approach was applied with only one seed point per voxel in which the step size was 1 mm (37). The maxi-
mal angle between two consecutive tract directions was set to 20° and an FA threshold of 0.3 was used during tractography, as in Van Hecke et al (26), Tsuchiya et al (38) and Melhem et al (39). Subsequently, all quantita-
tive diffusion parameters of interest are selected on the tracts. The tractography parameters were defined as in Van Hecke et al, and a careful visual inspection was performed to make sure that the whole spinal cord was covered by fiber tracts without any interruptions in all subjects (26). Diffusion tensor tractography is thus used to further segment the spinal cord tissue, using the orientational diffusion information that is present in each voxel. The spinal cord was thereby initially separated from the background noise by drawing an ROI on every axial slice. Multiple ROIs were used to make sure the whole cervical spinal cord was included in the analysis.

The diffusion properties of the MS lesions and the NAWM in the patients with MS lesions were also evaluated. The MS lesions were identified on the anatomical MR images that were acquired at exactly the same cord levels as the diffusion tensor data sets. The ROIs that were used to delineate the lesions on the anatomical MR images were transferred to the DTI data set to ob-
tain the diffusion properties. Analogously, ROIs were drawn on the conventional MR images to delineate the NAWM tissue and subsequently transferred to the DTI data set. As in the work of Filippi et al., spinal cord tissue was assigned to be normal appearing when no lesion was found in the adjacent slices (40).

Statistical Analysis Procedures

Statistical tests were performed with the SPSS analysis package (http://www.spss.com). Male and female data sets were combined because a t-test showed no differ-
ence in any of the diffusion parameters between both sexes ($P >> 0.05$, with 16 males versus 26 females). Moreover, the age distribution in the three subject groups was not significantly different for both sexes ($P >> 0.05$, with 16 males versus 26 females).

An analysis of covariance (ANCOVA) was used to compare the cervical cord diffusion properties from the control subject group with both MS patient groups. Kolmogorov-Smirnov tests demonstrated that a para-
metric approach could be applied ($P >> 0.05$). Poten-
tially confounding factors, such as the subject’s age and the cross-sectional area of their cervical spinal cord—measured as the number of selected voxels—were included in the ANCOVA model. Although the age and the cross-sectional area were not differently dis-
tributed in the different subject groups, both factors were included in the analysis of covariance. Differences in diffusion measures between groups could, therefore, be attributed to an intrinsic difference between the dif-
sion properties of the subjects groups. In this context, the cervical spinal cord cross sectional area $A$ was cal-
culated separately for both image analysis approaches.

Figure 1. A contour that deline-
ates the spinal cord is drawn

the online issue, which is avail-
able at www.interscience.wiley.
com.]
as the number of selected voxels for analysis. In addition, the statistical results were adjusted to correct for multiple comparisons using Fisher’s least significant difference approach.

The intra-observer reproducibility of the different image analysis methods was tested using the intra-class correlation coefficient (ICC). To this end, the ROIs were drawn a second time by the same observer. A measurement is deemed highly reproducible if ICC > 0.9. In the case of 0.7 < ICC < 0.9, the reproducibility is considered acceptable. Finally, results with an ICC < 0.7 are interpreted as poorly reproducible.

RESULTS

Using the ROI approach, a mean cross sectional surface A of 80.3 mm², 70.7 mm², and 75.4 mm² was observed for the control group, the MS patient group with lesions, and the MS patient group without spinal cord lesions, respectively (see Table 1; Fig. 3). Although larger cross-sectional

sectional areas of 89.2 mm$^2$, 79.9 mm$^2$, and 82.0 mm$^2$ were found for the different subject groups using the tractography-based image analysis method (see Table 1: Fig. 3). Pearson correlation tests demonstrated a significant correlation between the cross-sectional areas of the ROI- and the tractography-based approach ($P << 0.001$; $r > 0.9$, results not shown). These results suggest that a smaller cross sectional area of the spinal cord can be observed in the MS patient groups compared with the control group. However, this difference was not found to be statistically significant, as can be observed in Table 2.

The cervical spinal cord diffusion metrics of the different subject groups are presented for the ROI- and the tractography-based image analysis approaches in Table 1. The distribution of these diffusion measures is visualized using boxplots in Figure 3, whereby the boxplots of the control group, the MS group with spinal cord lesions, and the MS group without known spinal cord lesions are colored in green, red, and orange, respectively. The results of ANCOVA tests, which compare the diffusion measures across the different subject groups, thereby taking into account the subject age and the cross-sectional spinal cord area, are displayed in Table 2. It can be observed that the FA, the transverse diffusivity $\lambda_\perp$, and the ratio of the longitudinal and transverse diffusivities ($\lambda / \lambda_\perp$) are significantly lower for the MS patients with spinal cord lesions compared with the control subjects using the ROI method ($P = 0.014$, $P = 0.028$, and $P = 0.039$, respectively) and the tractography-based approach ($P = 0.006$, $P = 0.037$, and $P = 0.012$, respectively). Although the visual results of Figure 3 suggest an increased MD in the MS patient group with spinal cord lesions, no statistically significant difference in MD was found (Table 2).

The FA and the $\lambda / \lambda_\perp$ values were significantly different between the control group and the MS patient group without spinal cord lesions. These FA differences are statistically significant with a $P$ value of 0.013 for both image analysis methods (Table 2). For $\lambda / \lambda_\perp$, a $P$ value of 0.018 and 0.020 was found for the ROI- and the tractography-based method, respectively. The diffusion values of the MS patients without spinal cord lesions were not observed to be different from the diffusion measures of the MS patients with spinal cord lesions (see Fig. 1, statistical results not shown). In addition to the study of the NAWM of MS patients without spinal cord lesions, the NAWM diffusion measures of MS patients with spinal cord lesions are examined. To this end, the lesions and the NAWM were separated manually by ROIs. As can be observed in Table 4, all diffusion measures are significantly different in the spinal cord plaques compared with the measures of the control subjects.

No statistical difference was observed between the cervical spinal cord diffusion measures of patients with and without spinal cord lesions using both postprocessing methods ($P >> 0.05$). In addition, no diffusion differences were found between the NAWM of the patients with and without spinal cord lesions.

Finally, the reproducibility of image processing methods is examined using the intra-class correlation coefficient. As can be observed in Table 3, the ICC is very high for the tractography-based method. Because the ROI approach is more user dependent due to the manual delineation of the ROIs, lower ICC values were observed (see Table 3). Although these ICC values (0.66–0.85) represent an acceptable reproducibility, the observer-dependent affects the statistical results of the ROI analysis (see Table 2).

**DISCUSSION**

Conventional MR is used in daily clinical routine to detect spinal cord lesions in patients with MS. However, it has been demonstrated that findings on conventional MR scans do not always correlate well with the clinical status of the MS patients (41,42). In addition, previous studies did not find a correlation between the clinical disability of MS patients and the number and extent of the spinal cord lesions that were detected on MR (43–46). Because DTI provides information about the microstructural WM organization, the resulting diffusion metrics are potentially more sensitive to detect spinal cord involvement in MS patients than conventional MR.

In this work, the spinal cord of MS patients without any lesions on the conventional MR scans is studied with DTI. To the best of our knowledge, all DTI studies of the spinal cord in MS patients evaluated the diffusion metrics in spinal cord lesions or in NAWM in the proximity of lesions. Our results suggest that the FA and the ratio of the longitudinal and transverse eigenvalues are significantly reduced in the spinal cord of MS patients without lesions (see Fig. 3; Tables 1, 2). These results were confirmed by the analysis of the NAWM in the spinal cord with lesions (see Table 4). In concordance with the literature, the FA was found to be significantly reduced in the MS patients with spinal cord lesions compared with the FA of the age- and sex-matched control subjects (15–22). In addition, a significant increase of the transverse eigenvalues and decrease of the ratio of the longitudinal and transverse eigenvalues was observed in the spinal cord of these MS patients compared with the control subjects. Within the spinal cord lesions, the FA and the ratio of the longitudinal and transverse eigenvalues were decreased and the MD, the longitudinal, and transverse eigenvalues were increased, compared with the diffusion measures of the healthy spinal cord tissue of the control subjects.

In agreement with the literature, our results suggest that the FA and the ratio of the longitudinal and transverse diffusivities are the most sensitive diffusion measures to detect microstructural alterations that are induced by the MS disease process. These differences were observed in the NAWM and the lesions of MS patients with $T_2$ spinal cord lesions and in the NAWM of MS patients without $T_2$ spinal cord lesions (see Tables 2, 4). Additionally, an increased MD, longitudinal diffusivity, and transverse diffusivity was observed within the spinal cord lesions. A recent postmortem study, which correlated diffusion measures with the myelin content and the axonal count, suggested that an FA decrease and a MD increase is primary correlated with loss of myelin (47). Recent studies using animal models further demonstrated that a loss of axons is repre-
method. This suggests that the microstructural damage in the spinal cord of MS patients is not significantly different in patients with lesions compared with patients without lesions. Here, we want to stress that our results should be interpreted cautiously, given that our study may have been limited by the relatively small number of subjects.

The magnitude of the quantitative diffusion measures that were found in this study (see Table 1), are within the range of the previously reported values (see Table 5). Notice that a large variability exists in the FA and MD measures across different studies (15–21). This is probably due to disease heterogeneity in the different groups (different age range, disease state, and so on), the use of different image acquisition and analysis methods, and the relatively low reproducibility of some of these methods. All previous DTI studies of the spinal cord of MS patients reported a statistically significant FA difference between the control group and the MS patient group, whereas MD was only found to be different in some studies. In addition to the group and disease heterogeneity and the use of various image analysis methods, the application of different statistical methods and post hoc tests, and the incorporation of various cofactors in the statistics can explain the differences in the reported P values. Different cofactors, such as the age of the subjects and the cross-sectional area of the spinal cord were incorporated in the statistics.

Because it is known that these factors can affect diffusion values of the spinal cord (26).

Because many spinal cord voxels are affected by different degrees of partial volume averaging with CSF it is not straightforward to reliably select the relevant spinal cord voxels of interest in the different subjects. Some studies evaluate histogram information originating from the central part of the spinal cord (16–18). In this approach, a lot of valuable information is discarded. In addition, the sensitivity to find differences between control subjects and MS patients can be reduced, because Hesseltine et al demonstrated that only minor differences were found in the central part of the spinal cord, which mainly consists of grey matter (19). Most of the studies use an ROI-based approach to obtain diffusion data. However, it has been demonstrated that the reproducibility of this method can be very low (26). Although the ICC values that were found in this study were acceptable (see Table 3), the statistical results and conclusions differed significantly when the ROIs were drawn a second time by the same observer (see Table 2). In this context, there is a need for a standardized approach for analyzing spinal cord DTI data, which, in our opinion, is provided by diffusion tensor tractography-based segmentation. In contrast to studies that incorporated diffusion tensor tractography results of the spinal cord to provide quantitative information regarding the fiber architecture, tractography was applied in this study to provide quantitative diffusion information regarding the WM damage induced in the spinal cord of patients with MS (38,50–54). Compared with the ROI method, an observer dependency is replaced by a parameter dependency of the tractography algorithm, resulting in a more reproducible and standardized measurement of the diffusion characteristics (see Table 3).

Because the application of tractography in the spinal cord might be limited over large distances, we opted for drawing ROIs on every axial slice.

A standard acquisition scheme was used, which is available on most scanners in a clinical setting, without the need of specific hardware. In addition, isotropic voxels were acquired to reduce the FVE of spinal cord tissue with the surrounding CSF in the slice direction. However, due to the limited in-plane resolution, it was hard to separate WM and GM. In addition, other reported modifications of the DTI acquisition scheme might improve image quality and, therefore, the reliability of the subsequent analysis. For example, studies have focused on the optimization of the DTI acquisition with respect to bulk motion and pulsatile flow artifacts from the surrounding CSF (55–59). Other studies used cardiac gating and interleaved echo-planar diffusion imaging to reduce motion artifacts and scan time, respectively (60,61). Line scan imaging is a fast technique that relies on the acquisition of columns (57,62). The advantage of our work is that it uses a standard, widely available acquisition scheme with isotropic voxels. 60 diffusion directions were used to increase the SNR and the reliability of our estimated diffusion measures to perform tractography reliably (27). Another limitation of our study is that no correlation was made of the diffusion metrics with clinical symptoms, as measured for example by the Expanded Disability Status Scale (EDSS) (63). However, the primary aim of our study was to demonstrate the feasibility and potential of the tractography-based segmentation approach to evaluate the spinal cord damage of MS patients and to investigate the diffusion measures of MS patients without T2 spinal cord lesions. The correlation of the diffusion metrics with the clinical status of the patients is already thoroughly reported in earlier studies (16–18,21). We also acknowledge the fact that some distortions might still be present in our data sets. We tried to correct for geometrical and motion distortions using a nonlinear image registration. However, such an automated correction did not lead to improved results (as determined by the residuals from the diffusion tensor fit), due to the relatively low amount of image information. In addition, no cardiac gating was used during the image acquisition.

We believe that our results demonstrate that diffusion tensor tractography has the potential to be used a standardized segmentation tool of spinal cord DTI images for the interpretation of NAWM results in MS patients. We also acknowledge that our findings are by no means conclusive and that our results should be interpreted cautiously, given that our study may have been limited by the relatively small number of subjects.

In conclusion, diffusion measures of the normal appearing white matter were evaluated in MS patients without spinal cord lesions. A reduced FA and ratio of the longitudinal and the transverse eigenvalues was observed in the spinal cord of MS patients without any detected spinal cord lesion on a conventional MR scan. These results, therefore, suggest that the spinal cord is not preserved in MS when lesions are only detected in the brain. Furthermore, this confirms previous findings, which demonstrated that DTI is more sensitive compared with conventional MR imaging in assessing the tissue damage in MS patients. In addition, we demonstrated that diffusion tensor tractography is a robust tool to analyze the spinal cord of MS patients and that the use of tractography is more reproducible and reliable compared with an ROI analysis to evaluate the diffusion measures of the spinal cord.
